Abstract

The paradigm of phenotypic plasticity indicates reversible relations of different cancer cell phenotypes, which extends the cellular hierarchy proposed by the classical cancer stem cell (CSC) theory. Since it is still questionable if the phenotypic plasticity is a crucial improvement to the hierarchical model or just a minor extension to it, it is worthwhile to explore the dynamic behavior characterizing the reversible phenotypic plasticity. In this study we compare the hierarchical model and the reversible model in predicting the cell-state dynamics observed in biological experiments. Our results show that the hierarchical model shows significant disadvantages over the reversible model in describing both long-term stability (phenotypic equilibrium) and short-term transient dynamics (overshoot) of cancer cells. In a very specific case in which the total growth of population due to each cell type is identical, the hierarchical model predicts neither phenotypic equilibrium nor overshoot, whereas the reversible model succeeds in predicting both of them. Even though the performance of the hierarchical model can be improved by relaxing the specific assumption, its prediction to the phenotypic equilibrium strongly depends on a precondition that may be unrealistic in biological experiments, and it also fails to capture the overshoot of CSCs. By comparison, it is more likely for the reversible model to correctly describe the stability of the phenotypic mixture and various types of overshoot behavior.

1 Introduction

The cancer stem cell theory has provided a hierarchical model of how diverse cancer cells being organized [1, 2, 3]. Similar to the stem cell theory in normal tissues, this hierarchical model assumes that a small number of stem-like cancer cells (termed cancer stem cells, CSCs) are capable of self-renewal and differentiation into other more committed cancer cells (termed non-stem cancer cells, NSCCs) but not vice versa. That is, CSCs are thought to be at the apex of this cellular hierarchy. However, some recent researches may extend this unidirectional relation of cancer cells. It has been reported that cancer cells can convert from NSCC phenotype to CSC phenotype (*e.g.* breast cancer [4, 5], melanoma [6], colon cancer [7] and glioblastoma multiforme [8]). Furthermore, the interconversions among cancer cell phenotypes have also been found (breast cancer [9]). All these works indicate reversible relations of different cancer cells (termed *phenotypic plasticity*, which has long been an issue concerned in bacterial populations [10]).

Very recently special attention has already been paid to the reversible cancer models with the phenotypic plasticity by theoreticians. In particular, dos Santos and da Silva explained the variable frequencies of CSCs in tumors by establishing a model with stochastic cell plasticity [11, 12]. Leder *et al* investigated the model of reversible conversions between the stem-like resistant cells (SLRCs) and the differentiated sensitive cells (DSCs)

Figure 1: Overshoot is a type of non-monotonic phenomenon [20] that, starting from a state that is lower than the equilibrium level, the process first increases above the final equilibrium level and then gradually decreases to it.

in glioblastomas [13]. Wang *et al* showed how tumor heterogeneity arises in the model of cooperating CSC hierarchy with cell plasticity [14]. Zhou *et al* showed that the de-differentiation from NSCC phenotype to CSC phenotype was essential for explaining the transient increase of the minority populations of CSCs observed in cancer cell lines [15, 16]. Chen *et al* studied stochastic models that capture the transitions between endocrine therapy responsive and resistant states of breast cancer cells [17]. Zhou *et al* investigated nonequilibrium dynamics with phenotype transitions of cancer cells [18]. Jilkin and Gutenkunst studied the effect of de-differentiation on time to mutation acquisition in cancers [19].

However, it is still questionable if the phenotypic plasticity is a crucial improvement to the hierarchical model or just a minor extension to it [21, 22]. Thus a rigorous analysis on the characteristics owned by the model with the phenotypic plasticity is necessary for model validation. In this study, we try to investigate this issue by giving a comparative study of the reversible model and the hierarchical model. Note that Gupta *et al* studied SUM149 and SUM159 breast cancer cell lines [9], in which two interesting phenomena were observed: *phenotypic equilibrium* and *overshoot*. For the phenotypic equilibrium, they found that the breast cancer cell lines will tend to a stable phenotypic mixture over time regardless of initial states. Similar results on the phenotypic equilibrium were also reported in [23, 24, 7]. For the overshoot, they found that shortly after the cell sorting, the proportion of the minority subpopulation will increase transiently above the final equi-

librium level, and then decrease to it (Fig. 1). Enlightened by these observations, we show that the reversible model is more capable of capturing the phenotypic equilibrium and overshoot than the hierarchical model. Under a very specific assumption that the total population growth due to each cell phenotype is identical, the hierarchical model can perform neither phenotypic equilibrium nor overshoot, whereas the reversible model succeeds in predicting both the phenotypic equilibrium and three types of overshoots (asynchronous, synchronous and oscillating overshoots). Even though the performance of the hierarchical model can be improved by relaxing the specific assumption, it is still not good enough to correctly capture the cell-state dynamics. On one hand, the phenotypic equilibrium predicted by the hierarchical model strongly depends on the condition that the self-contributed growth rate by CSCs is faster than that of more committed cancer cells. However, it has been reported that this condition cannot be satisfied in some cancers [25, 26]. On the other hand, by fitting the two models to experimental data in [9], the hierarchical model can only fit the overshoot of NSCCs, but it cannot capture the overshoot of CSCs. By contrast, the reversible model can fit both of them. Therefore, our results generally imply that the reversible model shows distinct advantages over the hierarchical model in predicting both long-term and transient dynamics of cancer cells.

The paper is organized as follows. The mathematical model is presented in Section 2. Main results are shown in Section 3, where we give a comparative study of the reversible and hierarchical models. Conclusions are presented in Section 4.

2 Model

In this section we describe the assumptions of our model. We model cancer as population dynamics of cancer cells, each cancer cell can be assigned to one of the following cell phenotypes: CSC_0 , $NSCC_1$, $NSCC_2$, ..., and $NSCC_n$. Let $X_0(t)$, $X_1(t)$, ..., $X_n(t)$ be the cell numbers of CSC_0 , $NSCC_1$, ..., $NSCC_n$ at time t respectively, then the model can be described as a cellular dynamical system of $\vec{X}_t = (X_0(t), X_1(t), \dots, X_n(t))^T$. In particular, the model will reduce to a two-phenotypic model when $n = 1$. That is, besides CSC-phenotype, all the other cancer cells are grouped into one whole NSCC-phenotype. This CSC-NSCC model has extensively been investigated in previous literature [21, 11, 12, 15, 13, 14]. Here we pay more attention to the multi-phenotypic case ($n \geq 2$). As a starting point, the case with $n = 2$ should be a natural and favorable candidate for theoretical analysis. Meanwhile, motivated by Gupta *et al* [9] where three phenotypes (stem-like, basal and luminal) were identified, we are concerned about CSC_0 - $NSCC_1$ - $NSCC_2$ model in light of both theoretical and experimental reasons. Unlike the three-phenotypic cell lineages investigated in [27, 28, 29] where cancer stem cells, progenitor cells, and terminally differentiated cells are hierarchically cascaded, here we are

more interested in the cell population structure investigated in [9]. In their work, CSCs can differentiate into NSCC₁ and NSCC₂, respectively. They were not assumed to be cascaded. Moreover, by the phenotypic plasticity, they can interconvert into each other and de-differentiate into CSCs.

We now present the cellular processes included in our model. For CSC₀, it can not only divide symmetrically into two identical CSC₀ daughters, but also divide asymmetrically into CSC₀ and NSCC_{*i*} (*i* = 1 or 2) [30, 31, 32]. That is,

- $CSC_0 \xrightarrow{\alpha_1} CSC_0 + CSC_0$.
- $CSC_0 \xrightarrow{\alpha_2} CSC_0 + NSCC_1$.
- $CSC_0 \xrightarrow{\alpha_3} CSC_0 + NSCC_2$ ¹.

For NSCC₁ and NSCC₂, besides the phenotypic plasticity, they can also perform symmetric divisions and cell death. That is,

- $NSCC_1 \xrightarrow{\beta_1} NSCC_1 + NSCC_1$;
- $NSCC_1 \xrightarrow{\beta_2} CSC_0$;
- $NSCC_1 \xrightarrow{\beta_3} NSCC_2$;
- $NSCC_1 \xrightarrow{\beta_4} \emptyset$;
- $NSCC_2 \xrightarrow{\gamma_1} NSCC_2 + NSCC_2$;
- $NSCC_2 \xrightarrow{\gamma_2} CSC_0$;
- $NSCC_2 \xrightarrow{\gamma_3} NSCC_1$;
- $NSCC_2 \xrightarrow{\gamma_4} \emptyset$.

Based on the above cellular processes, the dynamics of $\vec{X}_t = (X_0, X_1, X_2)^T$ can be captured by the following ordinary differential equations (ODEs)

$$\begin{cases} \frac{dX_0}{dt} = \alpha_1 X_0 + \beta_2 X_1 + \gamma_2 X_2 \\ \frac{dX_1}{dt} = \alpha_2 X_0 + (\beta_1 - \beta_2 - \beta_3 - \beta_4) X_1 + \gamma_3 X_2 \\ \frac{dX_2}{dt} = \alpha_3 X_0 + \beta_3 X_1 + (\gamma_1 - \gamma_2 - \gamma_3 - \gamma_4) X_2 \end{cases} \quad (1)$$

¹It should be pointed out that, the symmetric differentiation “ $CSC_0 \rightarrow NSCC_i + NSCC_i$ ” is also an important type of transition [33] that should be considered in the model. However, it can be shown that the main results we are interested in this work can still hold (with only minor changes in proofs) even if adding this transition into Eq. (1). Therefore, to keep the model as minimal as possible, the symmetric differentiation is not included in presented model.

By letting

$$Q = [q_{ij}] = \begin{pmatrix} \alpha_1 & \beta_2 & \gamma_2 \\ \alpha_2 & \beta_1 - \beta_2 - \beta_3 - \beta_4 & \gamma_3 \\ \alpha_3 & \beta_3 & \gamma_1 - \gamma_2 - \gamma_3 - \gamma_4 \end{pmatrix}, \quad (2)$$

Eq. (1) can be expressed as

$$\frac{d\vec{X}_t}{dt} = Q\vec{X}_t. \quad (3)$$

For this model, we have the following remarks:

(1) Each element q_{ij} of Q can be seen as the per capita growth rate of i^{th} phenotype contributed by j^{th} phenotype. Let us take the first row of Q as an example. α_1 is the symmetric division rate of CSC_0 , thus the growth rate of X_0 due to CSC_0 themselves can be expressed as $\alpha_1 X_0$; β_2 and γ_2 are the de-differentiation rates from $NSCC_1$ and $NSCC_2$ respectively, so the growth rate of X_0 due to $NSCC_1$ and $NSCC_2$ is $\beta_2 X_1 + \gamma_2 X_2$. In this way, it is easy to explain the biological meaning of “ $dX_0/dt = \alpha_1 X_0 + \beta_2 X_1 + \gamma_2 X_2$ ”, *i.e.* the rate of change of X_0 is the sum of the growth rates contributed by all the three cell phenotypes in the population. Similarly, we can explain the other two equations in Eq. (1).

(2) Note that $\beta_2, \beta_3, \gamma_2$ and γ_3 are the parameters associated with the phenotypic plasticity, the model will reduce to the hierarchical model by letting them be zero. Accordingly, Q will become to a lower-triangular matrix

$$Q^* = [q_{ij}^*] = \begin{pmatrix} \alpha_1 & 0 & 0 \\ \alpha_2 & \beta_1 - \beta_4 & 0 \\ \alpha_3 & 0 & \gamma_1 - \gamma_4 \end{pmatrix}. \quad (4)$$

(3) Let $W = X_0 + X_1 + X_2$ be the total number of the population, then

$$\frac{dW}{dt} = (\alpha_1 + \alpha_2 + \alpha_3)X_0 + (\beta_1 - \beta_4)X_1 + (\gamma_1 - \gamma_4)X_2. \quad (5)$$

Note that the coefficient of each X_i on right-hand side of Eq. (5) is just the the sum of the corresponding column in Q , *i.e.* the per capita growth rate of the whole population due to X_i . In particular, when

$$\alpha_1 + \alpha_2 + \alpha_3 = \beta_1 - \beta_4 = \gamma_1 - \gamma_4 = \kappa, \quad (6)$$

the growth rate of the whole population due to each phenotype will be identical. This special case implies meaningful biological significance and has been reported in some

cancer cell lines (breast cancer [9] and colon cancer [15]). In this case Eq. (5) will reduce to a very simple form

$$\frac{dW}{dt} = \kappa W,$$

that is, W will grow exponentially with constant rate. We will show that, even in this special case the reversible model and the hierarchical models are quite different in predicting the phenotypic equilibrium and overshoot. For convenience, we denote

$$A_1 = \alpha_1 + \alpha_2 + \alpha_3, \quad (7)$$

$$A_2 = \beta_1 - \beta_4, \quad (8)$$

$$A_3 = \gamma_1 - \gamma_4. \quad (9)$$

(4) Note that all the parameters are assumed to be constant. In other words, there is no feedback control included in presented model. This is of course a simplification of the biological facts. To model real biological systems, feedback mechanisms are indispensable [34, 35, 36, 28]. However, we will show that our model is not overly simplistic to characterize the phenotypic plasticity in comparison to the cellular hierarchy.

In the remaining of this section, we will convert the cell number equations Eq. (1) into the following cell proportion equations Eq. (10). This is because in reality, relative cell numbers, rather than absolute cell numbers, are usually measured by fluorescence-activated cell sorting (FACS) experiments. Let $x_0 = X_0/W$, $x_1 = X_1/W$ and $x_2 = X_2/W$, by variable substitutions in Eq. (1) we have

$$\begin{cases} \frac{dx_0}{dt} = \alpha_1 x_0 + \beta_2 x_1 + \gamma_2 x_2 - x_0(A_1 x_0 + A_2 x_1 + A_3 x_2) \\ \frac{dx_1}{dt} = \alpha_2 x_0 + (\beta_1 - \beta_2 - \beta_3 - \beta_4) x_1 + \gamma_3 x_2 - x_1(A_1 x_0 + A_2 x_1 + A_3 x_2) \\ \frac{dx_2}{dt} = \alpha_3 x_0 + \beta_3 x_1 + (\gamma_1 - \gamma_2 - \gamma_3 - \gamma_4) x_2 - x_2(A_1 x_0 + A_2 x_1 + A_3 x_2) \end{cases} \quad (10)$$

Note that $x_0 + x_1 + x_2 = 1$, the freedom of Eq. (10) is actually two. By letting $x_2 = 1 - x_0 - x_1$, Eq. (10) can be transformed into

$$\begin{cases} \frac{dx_0}{dt} = -(A_1 - A_3)x_0^2 - (A_2 - A_3)x_0 x_1 + A_4 x_0 + A_5 x_1 + \gamma_2 \\ \frac{dx_1}{dt} = -(A_2 - A_3)x_1^2 - (A_1 - A_3)x_0 x_1 + A_6 x_0 + A_7 x_1 + \gamma_3 \end{cases} \quad (11)$$

where

$$A_4 = \alpha_1 - (\gamma_1 - \gamma_4) - \gamma_2, \quad (12)$$

$$A_5 = \beta_2 - \gamma_2, \quad (13)$$

$$A_6 = \alpha_2 - \gamma_3, \quad (14)$$

$$A_7 = (\beta_1 - \beta_2 - \beta_3 - \beta_4) - (\gamma_1 - \gamma_4) - \gamma_3. \quad (15)$$

When $\beta_2 = \beta_3 = \gamma_2 = \gamma_3 = 0$, *i.e.* the phenotypic conversion rates are set to be zero, we have

$$\begin{cases} \frac{dx_0}{dt} = -(A_1 - A_3)x_0^2 - (A_2 - A_3)x_0x_1 + A'_4x_0 + A'_5x_1 \\ \frac{dx_1}{dt} = -(A_2 - A_3)x_1^2 - (A_1 - A_3)x_0x_1 + A'_6x_0 + A'_7x_1 \end{cases} \quad (16)$$

where

$$A'_4 = \alpha_1 - (\gamma_1 - \gamma_4), \quad (17)$$

$$A'_5 = 0, \quad (18)$$

$$A'_6 = \alpha_2, \quad (19)$$

$$A'_7 = (\beta_1 - \beta_4) - (\gamma_1 - \gamma_4). \quad (20)$$

We term Eq. (11) the *reversible model*, and term Eq. (16) the *hierarchical model*. The comparison of these two models is the main task in the following section.

In this section we try to give a comparative study of Eqs. (11) and (16).

One trivial difference between the two models happens when there is no CSC in the initial population. In this case, since in the hierarchical model CSCs cannot be spontaneously created by other cell phenotypes, there is no CSC in the population all the time, whereas new-born CSCs can be generated from NSCCs in the reversible model. However, in reality it is quite impossible to completely purify cancer cell lines without any CSCs by cell sorting. Based on this fact, we only discuss the cases with positive initial states of CSCs afterwards. Both long-term stable behavior and short-term transient dynamics are investigated when comparing the two models. Enlightened by [9], we are particularly concerned about their predictions to the phenotypic equilibrium and overshoot.

2.1 Special case

Before exploring the general models in Eqs. (11) and (16), we first discuss a very specific case with $A_1 = A_2 = A_3$. Investigating this special case can provide some valuable insights to the general analysis.

For the hierarchical model in this case,

$$\begin{cases} \frac{dx_0}{dt} = A'_4 x_0 \\ \frac{dx_1}{dt} = A'_6 x_0 \end{cases} \quad (21)$$

It is easy to give their explicit solutions

$$\begin{cases} x_0(t) = x_0(0)e^{-(\alpha_2+\alpha_3)t} \\ x_1(t) = \frac{\alpha_2}{\alpha_2+\alpha_3}x_0(0)(1 - e^{-(\alpha_2+\alpha_3)t}) + x_1(0) \end{cases} \quad (22)$$

where $x_0(0)$ and $x_1(0)$ are the initial states. So we have

1. Since $x_0(t)$ and $x_1(t)$ are both monotonic functions of t , they cannot perform overshoot.
2. Note that

$$\begin{aligned} \lim_{t \rightarrow +\infty} x_0(t) &= 0, \\ \lim_{t \rightarrow +\infty} x_1(t) &= \frac{\alpha_2}{\alpha_2 + \alpha_3}x_0(0) + x_1(0), \end{aligned}$$

CSCs proportion will eventually be zero, and the equilibrium proportions of x_1 depends on the initial states. Note that the phenotypic equilibrium corresponds to the stabilization of the phenotypic *mixture* that is *independent* of the initial states [9], the hierarchical model fails to predict the phenotypic equilibrium.

We turn our attention to the reversible model

$$\begin{cases} \frac{dx_0}{dt} = A_4 x_0 + A_5 x_1 + \gamma_2 \\ \frac{dx_1}{dt} = A_6 x_0 + A_7 x_1 + \gamma_3 \end{cases} \quad (23)$$

For the phenotypic equilibrium, we have the following theorem:

Theorem 1. *There exists unique stable fixed point $E = (x_0^*, x_1^*)$ in Eq. (23), where*

$$x_0^* = \frac{A_5 \gamma_3 - A_7 \gamma_2}{A_4 A_7 - A_5 A_6} > 0, \quad x_1^* = \frac{A_6 \gamma_2 - A_4 \gamma_3}{A_4 A_7 - A_5 A_6} > 0.$$

Table 1: The overshoot predicted by the special reversible model

	Parameters	Behavior
1	$\Delta > 0$	no overshoot, asynchronous and synchronous overshoots
2	$\Delta = 0$ and A is diagonalizable	no overshoot
3	$\Delta = 0$ and A is not diagonalizable	asynchronous and synchronous overshoots
4	$\Delta < 0$	oscillating overshoot

The proof is put in A. Theorem 1 indicates that the phenotypic equilibrium naturally holds in the special reversible model. We now consider whether this model can perform overshoot. The main results are listed in Table 1 (see B for more details). In particular, Fig. 2 illustrates the predictions by case 1 ($\Delta > 0$):

- *Non-overshoot (left panel)*. Both x_0 and x_1 are monotonic functions.
- *Asynchronous overshoot (middle panel)*. Either x_0 or x_1 can perform overshoot (The figure shows an example of x_0 -overshoot), but they cannot perform overshoot simultaneously.
- *Synchronous overshoot (right panel)*. x_0 and x_1 can perform overshoot simultaneously.

Case 2 ($\Delta = 0$ and A is diagonalizable) is the *star* case (see B), overshoot can never happen. For case 3 ($\Delta = 0$ and A is not diagonalizable), it belongs to the *nodal* case (see B), both asynchronous and synchronous overshoots can happen. Besides, in case 4 ($\Delta < 0$), the model performs damped oscillatory dynamics, corresponding to an interesting *oscillating overshoot* (Fig. 3).

According to the above comparisons between Eqs. (21) and (23), the reversible model shows richer dynamics than the hierarchical model in performing both the phenotypic equilibrium and overshoot.

2.2 General case

We now remove the constraint of $A_1 = A_2 = A_3$ and further consider the general case in this section. For the general hierarchical model Eq. (16), the following theorem states the condition under which the phenotypic mixture will finally stabilize:

Theorem 2. *There exist three singular points in Eq. (16): $E'_0 = (0, 0)$, $E'_1 = (0, 1)$ and $E'_2 = (x_0^*, x_1^*)$, where*

$$x_1^* = \frac{A'_4 A'_6}{(A'_4 - A'_7)(A'_1 - A'_3) + A'_6 A'_7}, \quad x_0^* = \frac{(A'_4 - A'_7)x_1^*}{A'_6}.$$

Figure 2: Three types of predictions by the special reversible model in case 1 ($\Delta > 0$).

Figure 3: Oscillating overshoot: Compared to the simple uphill-downhill overshoot in Fig 1, oscillating overshoot shows multiple uphill-downhill movements with damped amplitude.

Assume that $\alpha_1 > \beta_1 - \beta_4$ and $\alpha_1 > \gamma_1 - \gamma_4$, $E'_2 = (x_0^*, x_1^*)$ is the unique stable fixed point.

The proof is put in C. Note that α_1 , $\beta_1 - \beta_4$ and $\gamma_1 - \gamma_4$ are the diagonal elements of the matrix Q^* in Eq. (4), representing the per capita growth rates due to the corresponding cell phenotypes themselves. Theorem 2 thus indicates that the general hierarchical model is capable of predicting the phenotypic equilibrium only provided that the self-contributed growth rate by CSCs is larger than that of more committed cancer cells. However, this condition may not be satisfied in reality. It has been reported that more committed cancer cells can have faster cycling time than stem-like cancer cells in some cancers [25, 26, 14]. In contrast, the following theorem shows the phenotypic equilibrium of the general reversible model Eq. (10):

Theorem 3. *The reversible model Eq. (10) has unique positive stable fixed point ².*

The proof is put in D. Theorem 3 shows that the result in the special case (Theorem 1) can be extended to the general case. By comparison of Theorems 2 and 3, we can see that it is more likely for the reversible model to correctly capture the phenotypic equilibrium.

In the remaining of this section, we discuss the overshoot performances of the two models by fitting them to the cell-state dynamics in [9]. We fitted Eqs. (16) and (10) to the SUM159 data shown in the Fig. 3 of [9]. From Fig. 4, we can see that the reversible model fits the data better than the hierarchical model. In particular, note that both the overshoots of luminal cells and stem-like cells were presented in the SUM159 data (see the left panel and right panel in the Fig. 3 of [9] respectively). Our result shows that, the reversible model can capture both of them, whereas the hierarchical model can only fit the overshoot of luminal cells but it fails to capture the overshoot of stem-like cells. In the left panel of Fig. 4, both the blue solid line (hierarchical model) and blue discrete triangle-marker line (reversible model) fit the overshoot of luminal cells. Meanwhile, in the right panel of Fig. 4, the red solid line (hierarchical model) shows a monotonic way up to the final equilibrium (non-overshoot), but the red discrete triangle-marker line (reversible model) predict the overshoot of stem-like cells.

Actually, it has already been reported in previous literature that the overshoot of NSCCs proportion can happen in classical CSC model [37], but the overshoot of CSCs proportion we think has added significance. Note that in the hierarchical model the increase of CSCs relies only on their self-renewals. When the initial fraction of CSCs is very limited, the transient increase of CSCs proportion should be very slow (constraint by the limitation of cell division cycle), so intuitively it is quite unlikely for the hierarchical model to capture the overshoot of CSCs proportion. In contrast, the de-differentiation

²We should point out that, to complete the final proof, technically it is necessary to add a small perturbation to the initial state in few cases, see D.

Figure 4: Predictions of the general hierarchical model and reversible model. We used least square method to fit the two models to the SUM159 data in [9]. The left panel shows the purified stem-like cell case, where the initial states of stem-like cells, basal cells and luminal cells were assumed to be 99%, 0.5% and 0.5% respectively. The right panel shows the purified luminal cell case, where the initial states of stem-like cells, basal cells and luminal cells were assumed to be 0.5%, 0.5% and 99% respectively. In both panels, the solid lines are the predictions by the hierarchical model, and the discrete triangle-marker lines are the predictions by the reversible model.

from NSCCs can effectively speed up the accumulation of CSCs, it is more likely for the reversible model to capture the overshoot of CSCs proportion. In other words, the overshoot of CSCs should be a better candidate than that of NSCCs to characterize the phenotypic plasticity. Our numerical result just supports this idea.

3 Conclusions

In this paper, we have tried to characterize the phenotypic plasticity by giving a comparative study between the reversible model and hierarchical model. According to our results, the reversible model shows richer dynamics and better predictions to experimental phenomena than the hierarchical model.

It should be noted that, to focus our attention to the reversible phenotypic plasticity, the presented model does not include the biologically complex mechanisms such as feedback controls and time delays. It is undeniable that, by including the feedback and delay mechanisms, the hierarchical model can also show complex dynamics that are beyond the

reach of the presented model [38, 39, 40, 34, 28]. For example, Bernard *et al* showed that oscillations can occur in their hierarchical model with feedbacks and delays [38]. Stiehl *et al* showed that the hierarchical model of hematopoiesis with nonlinear feedback can reproduce the overshoot and damped oscillations observed in clinical data [39]. We also think that the interplay between the feedback (or delay) mechanisms and the phenotypic plasticity should be a very interesting issue. As a starting point, it is suggested by our presented model that, the phenotypic plasticity facilitates the heterogeneity of cancer in two ways: it helps to sustain the coexistence of multiple phenotypes in cancer, and it also accelerates the recovery process of cancer stem cells in the population. These findings may shed some lights on the researches of the models incorporating the biological complexities with the phenotypic plasticity.

Moreover, the presented model is deterministic, whereby stochastic effects are not accounted for. Therefore, the branching model [41] concerning both the stochastic phenotypic conversions and proliferations of cancer cells is another interesting research direction. Finally, it is worth noting that, in addition to the long-term stabilization, the short-term transient dynamics also deserve special attention in the study of biological population dynamics [42]. In this work we have seen the significance of the overshoot in characterizing the phenotypic plasticity. It is interesting to explore more types of transient dynamics and their biological significance in future researches.

A Proof of Theorem 1

Theorem (page 9, Theorem 1). *There exists unique stable fixed point $E = (x_0^*, x_1^*)$ in Eq. (23), where*

$$x_0^* = \frac{A_5\gamma_3 - A_7\gamma_2}{A_4A_7 - A_5A_6} > 0, \quad x_1^* = \frac{A_6\gamma_2 - A_4\gamma_3}{A_4A_7 - A_5A_6} > 0.$$

Proof. Let

$$\begin{cases} A_4x_0 + A_5x_1 + \gamma_2 = 0 \\ A_6x_0 + A_7x_1 + \gamma_3 = 0, \end{cases} \quad (24)$$

where $A_4 = -(\alpha_2 + \alpha_3 + \gamma_2) < 0$, $A_7 = -(\beta_2 + \beta_3 + \gamma_3) < 0$, $A_5 = \beta_2 - \gamma_2$, $A_6 = \alpha_2 - \gamma_3$. Note that

$$A_4A_7 - A_5A_6 > A_5\gamma_3 - A_7\gamma_2 > 0, \quad A_4A_7 - A_5A_6 > A_6\gamma_2 - A_4\gamma_3 > 0,$$

it is easy to see that $E = (x_0^*, x_1^*)$ is the only fixed point. To proof the stability of E , let $x_0 = w_0 + x_0^*$, $x_1 = w_1 + x_1^*$, then Eq. (23) is transformed to

$$\begin{cases} \frac{dw_0}{dt} = A_4w_0 + A_5w_1 \\ \frac{dw_1}{dt} = A_6w_0 + A_7w_1 \end{cases} \quad (25)$$

Let $\vec{w} = (w_0, w_1)^T$ and

$$A = \begin{pmatrix} A_4 & A_5 \\ A_6 & A_7 \end{pmatrix}, \quad (26)$$

Eq. (25) can be expressed as

$$\frac{d\vec{w}}{dt} = A\vec{w}.$$

$E' = (0, 0)$ becomes the only fixed point and its characteristic equation is

$$\lambda^2 - (A_4 + A_7)\lambda + A_4A_7 - A_5A_6 = 0. \quad (27)$$

Since

$$\lambda_1 + \lambda_2 = A_4 + A_7 < 0, \quad \lambda_1\lambda_2 = A_4A_7 - A_5A_6 > 0,$$

the real parts of λ_1 and λ_2 are both negative. Hence E' is stable in Eq. (25), and then E is the unique stable fixed point of Eq. (23). The proof is completed. $\square$

B The overshoot predicted by the special reversible model

Let

$$\Delta = (A_4 - A_7)^2 + 4A_5A_6 \quad (28)$$

be the discriminant of (27). Since it has been shown that the real parts of λ_1 and λ_2 are negative, the special reversible model Eq. (23) can be classified into the following four cases (For the terminologies used below, please refer to Chapter 5 in [43]):

Figure 5: The phase diagrammatic sketch of the case that $\Delta = 0$ and A is diagonalizable.

Figure 6: The phase diagrammatic sketch of the case that $\Delta = 0$ and A is not diagonalizable. (a) Asynchronous overshoot: When starting from P_1 , x_0 can first exceed x_0^* and then decrease to it (overshoot), whereas x_1 cannot perform overshoot. However, when starting from P_2 , x_1 can perform overshoot, but x_0 cannot perform overshoot. That is, either x_0 or x_1 can perform overshoot, but they cannot perform overshoot simultaneously. (b) Synchronous overshoot: When starting from P_1 , both x_0 and x_1 can exceed E and then decrease to it. That is, they can perform overshoot simultaneously.

1. $\Delta > 0$. In this case the matrix A in Eq. (26) has two unequal negative eigenvalues. Thus E' is the *nodal point* of Eq. (25), correspondingly E is the *nodal point* of Eq.

(23). The solution can be expressed as

$$\vec{x} = P(e^{\lambda_1 t} k_1, e^{\lambda_2 t} k_2)^T, \quad (29)$$

where

$$P = \begin{pmatrix} p_{11} & p_{12} \\ p_{21} & p_{22} \end{pmatrix} \quad (30)$$

is a matrix determined by the coefficients of Eq. (25), both k_1 and k_2 are determined by the initial states. Different types of transient dynamics can happen for different parameter ranges. By numerical simulations, it is shown in Fig. 2 that the model can perform non-overshoot, asynchronous overshoot and synchronous overshoot respectively.

2. $\Delta = 0$ and A is diagonalizable. Since E is the *star point* in this case (Fig. B.5). There is no overshoot of x_0 and x_1 .
3. $\Delta = 0$ and A is not diagonalizable. In this case E is also called *nodal point*. From Fig. B.6, we can see that the model can perform both asynchronous and synchronous overshoots. If $(A_4 - A_7)/A_5 > 0$, the model can perform asynchronous overshoot (Fig. B.6(a)). If $(A_4 - A_7)/A_5 < 0$, the model can perform synchronous overshoot (Fig. B.6(b)).
4. $\Delta < 0$. A has two conjugate complex eigenvalues with negative real part. E is the *focal point*, resulting in oscillating overshoot (Fig. 3).

C Proof of Theorem 2

Theorem (page 12, Theorem 2). *There exist three singular points in Eq. (16): $E'_0 = (0, 0)$, $E'_1 = (0, 1)$ and $E'_2 = (x_0^*, x_1^*)$, where*

$$x_1^* = \frac{A'_4 A'_6}{(A'_4 - A'_7)(A'_1 - A'_3) + A'_6 A'_7}, \quad x_0^* = \frac{(A'_4 - A'_7)x_1^*}{A'_6}.$$

Assume that $\alpha_1 > \beta_1 - \beta_4$ and $\alpha_1 > \gamma_1 - \gamma_4$, $E'_2 = (x_0^*, x_1^*)$ is the unique stable fixed point.

Proof. To obtain the fixed points of Eq. (16), we consider

$$\begin{cases} -(A'_1 - A'_3)x_0^2 - (A'_2 - A'_3)x_0x_1 + A'_4x_0 = 0 \\ -(A'_2 - A'_3)x_1^2 - (A'_1 - A'_3)x_0x_1 + A'_6x_0 + A'_7x_1 = 0 \end{cases} \quad (31)$$

For the first equation $-(A'_1 - A'_3)x_0^2 - (A'_2 - A'_3)x_0x_1 + A'_4x_0 = 0$, we have either $x_0 = 0$ or $-(A'_1 - A'_3)x_0 - (A'_2 - A'_3)x_1 + A'_4 = 0$.

(i) When $x_0 = 0$, based on the second equation we have $x_1 = 0$ or $x_1 = A'_7/(A'_2 - A'_3) = 1$, that is, we have two fixed points

$$E'_0 = (0, 0), \quad E'_1 = (0, 1).$$

(ii) When $-(A'_1 - A'_3)x_0 - (A'_2 - A'_3)x_1 + A'_4 = 0$, the fixed point is

$$E'_2 = (x_0^*, x_1^*),$$

where

$$x_1^* = \frac{A'_4A'_6}{(A'_4 - A'_7)(A'_1 - A'_3) + A'_6A'_7}, \quad x_0^* = \frac{(A'_4 - A'_7)x_1^*}{A'_6}.$$

Since $\alpha_1 > \beta_1 - \beta_4$ and $\alpha_1 > \gamma_1 - \gamma_4$, we have $0 < x_0^* < 1$ and $0 < x_1^* < 1$. Let

$$f(x_0, x_1) = -(A'_1 - A'_3)x_0^2 - (A'_2 - A'_3)x_0x_1 + A'_4x_0,$$

$$g(x_0, x_1) = -(A'_2 - A'_3)x_1^2 - (A'_1 - A'_3)x_0x_1 + A'_6x_0 + A'_7x_1,$$

then

$$f'_{x_0} = -2(A'_1 - A'_3)x_0 - (A'_2 - A'_3)x_1 + A'_4, \quad f'_{x_1} = -(A'_2 - A'_3)x_0,$$

$$g'_{x_0} = -(A'_1 - A'_3)x_1 + A'_6, \quad g'_{x_1} = -2(A'_2 - A'_3)x_1 - (A'_1 - A'_3)x_0 + A'_7.$$

The Jacobian matrix of Eq. (16) is given by

$$J = \begin{pmatrix} f'_{x_0} & f'_{x_1} \\ g'_{x_0} & g'_{x_1} \end{pmatrix}.$$

Let us first consider the stability of $E'_0 = (0, 0)$,

$$J(E'_0) = \begin{pmatrix} A'_4 & 0 \\ A'_6 & A'_7 \end{pmatrix},$$

its characteristic equation is

$$(\lambda - A'_4)(\lambda - A'_7) = 0.$$

Note that

$$\alpha_1 > \beta_1 - \beta_4, \quad \alpha_1 > \gamma_1 - \gamma_4,$$

then $\lambda_1 = A'_4 > 0$, implying that $E'_0 = (0, 0)$ is unstable.

Similarly, for $E'_1 = (0, 1)$

$$J(E'_1) = \begin{pmatrix} A'_4 - A'_7 & 0 \\ A'_6 - A'_1 + A'_3 & -A'_7 \end{pmatrix},$$

$$(\lambda - (A'_4 - A'_7))(\lambda + A'_7) = 0,$$

$\lambda_1 = A'_4 - A'_7 > 0$, $E'_1 = (0, 1)$ is also unstable.

For $E'_2 = (x_0^*, x_1^*)$,

$$J(E'_2) = \begin{pmatrix} f_{x_0} & f_{x_1} \\ g_{x_0} & g_{x_1} \end{pmatrix},$$

where

$$f_{x_0} = f'_{x_0}(x_0^*, x_1^*), \quad f_{x_1} = f'_{x_1}(x_0^*, x_1^*), \quad g_{x_0} = g'_{x_0}(x_0^*, x_1^*), \quad g_{x_1} = g'_{x_1}(x_0^*, x_1^*).$$

Then we have

$$\lambda^2 - (f_{x_0} + g_{x_1})\lambda + f_{x_0}g_{x_1} - f_{x_1}g_{x_0} = 0,$$

$$\Delta = [-(\lambda_1 + \lambda_2)]^2 - 4\lambda_1\lambda_2 = A'^2_7 > 0,$$

$$\lambda_1 + \lambda_2 = A'_7 - 2A'_4 < 0,$$

$$\lambda_1\lambda_2 = A'_4(A'_4 - A'_7) > 0.$$

Then

$$\lambda_1 < 0, \quad \lambda_2 < 0.$$

It is shown that E'_2 is a stable nodal point, and then it is the unique stable fixed point in Eq. (16). The proof is completed. $\square$

D Proof of Theorem 3

Theorem (page 12, Theorem 3). *The reversible model Eq. (10) has unique positive stable fixed point.*

Proof. Our proof is valid for general multi-phenotypic cases, so in this section the dimension of the matrix Q in Eq (2) is not restricted to three any more, but n in general. Without loss of generality, we only prove the theorem when Q is positive (all the elements of Q are positive)³. According to the well-known Perron-Frobenius theory (see chapter 1 in [44]),

³Note that the off-diagonal elements of Q are positive, $Q + \tau I$ (I is the identity matrix) can be positive provided τ is large enough. It is easy to show that when λ is an eigenvalue of $Q + \tau I$, $\lambda - \tau$ is an eigenvalue of Q accordingly. That is, the eigenvalue structure of Q is the same as that of $Q + \tau I$. So we just need to consider $Q + \tau I$ instead of Q .

Q has a real eigenvalue λ_1 satisfying $\text{Re}\lambda < \lambda_1$ for any other eigenvalue λ of Q (called the Perron-Frobenius eigenvalue) and λ_1 is simple (a simple root of the characteristic equation of Q).

Since λ_1 is simple, the solution of Eq. (1) can be expressed as

$$\vec{X}_t = c_{1,1}\vec{u}e^{\lambda_1 t} + \sum_{j=2}^m \sum_{l=1}^{m_j} c_{j,l} \sum_{i=1}^{m_j} \vec{r}_{l,i}^j t^{i-1} e^{\lambda_j t}, \quad (32)$$

where $\lambda_1, \lambda_2, \dots, \lambda_m$ are the different eigenvalues of Q , m_j is the algebraic multiplicity of λ_j , $\vec{u}$ is the normalized ($u_1 + u_2 + \dots + u_n = 1$) right eigenvector of λ_1 , $\vec{r}_{l,i}^j$ is the corresponding eigenvector of λ_j , $c_{j,l}$ is determined by initial states. Suppose $c_{1,1} \neq 0$, since $\text{Re}\lambda_i < \lambda_1$ ($i \neq 1$),

$$\frac{\vec{X}_t}{c_{1,1}e^{\lambda_1 t}} = \vec{u} + \sum_{j=2}^n \sum_{l=1}^{n_j} \frac{c_{j,l}}{c_{1,1}} \sum_{i=1}^{n_j} \vec{r}_{l,i}^j t^{i-1} e^{(\lambda_j - \lambda_1)t} \rightarrow \vec{u}.$$

Thus

$$\vec{x}_t = \frac{\vec{X}_t}{W} = \frac{\vec{X}_t / c_{1,1}e^{\lambda_1 t}}{(X_1 + \dots + X_n) / c_{1,1}e^{\lambda_1 t}} \rightarrow \frac{\vec{u}}{u_1 + u_2 + \dots + u_n} = \vec{u}.$$

Noticing that Perron-Frobenius theory ensures that all the components of $\vec{u}$ are positive, i.e. $u > 0$.

Before we complete the proof, we need to discuss $c_{1,1} = 0$. In this case, the above method does not work. However, since fluctuations are inevitable in real world, $c_{1,1} = 0$ will hardly happen in reality. To show this, let $t = 0$ in Eq. (32)

$$c_{1,1}\vec{u} + \sum_{j=2}^n \sum_{l=1}^{n_j} c_{j,l} \vec{r}_{l,1}^j = \langle \vec{X}_0 \rangle^T$$

This is a linear equation of $c_{j,l}$. For $c_{1,1}$ we have

$$c_{1,1} = \frac{\det|B^*|}{\det|B|},$$

where $B = [\vec{u} \ r_{1,1}^2 \ r_{2,1}^2 \ \dots \ r_{n,1}^n]$, B^* is just B with its first column replaced by $\langle \vec{X}_0 \rangle^T$. It is easy to add a small perturbation $\varepsilon \vec{v}$ to $\langle \vec{X}_0 \rangle^T$, so that all the columns of B^* are linear independent, hence $c_{1,1} \neq 0$.
